Analysis of PS-Wave Birefringence from A 3-D/3-C Land Survey for Fracture Characterization

J. Gaiser and R. Van Dok; WesternGeco., 1625 Broadway, Suite 1300, Denver, Colorado, 80202, USA

Summary

An important application of 3-D converted P to S-waves (PS-waves) is to exploit S-wave birefringence (splitting) for delineating reservoir fractures. In azimuthally anisotropic media, fracture intensities and orientations are directly related to traveltime differences between the fast and slow S-wave and the polarization direction of the fast S-wave, respectively. Analysis techniques to help characterize a fracture setting are demonstrated using a 3-D data set from the Green River basin, Wyoming. Ratios of fast (PS1) and slow (PS2) average velocity are particularly important to identify the vertical extent of overburden anisotropy, as well as reservoir horizons. Overburden effects can be removed by 2Cx2C Alford rotation and layer-stripping analyses before characterizing deeper horizons. In addition, less quantitative attributes, which are very sensitive indicators of S-wave splitting, can be employed such as residual off-diagonal 2Cx2C amplitudes after overburden removal and isochron differences between PS1 and PS2.

Introduction

Converted waves are potentially very useful for fracture characterization because they enable exploiting the effects of birefringence on the upgoing shear waves (S-waves). Ata and Michelena (1995) acquired three 2-D lines centered on a well. Although the spatial coverage was sparse, azimuthal anisotropy appeared to be caused by two fracture systems. A small 3-D/3-C survey collected in the Wind River basin in Wyoming, to calibrate a larger P-wave effort, had some measure of success in characterizing fracture anisotropy (Gaiser, 1999; and Grimm et al., 1999). However, data quality was poor and azimuths were limited.

The objective of this study was to characterize fracture anisotropy in Cretaceous sandstone reservoirs located at depths between 3000 and 4500 m in the Green River basin using a 3-D/3-C survey. Care was taken in the survey design phase to insure good azimuth and offset coverage by having 14 live-receiver lines per swath spaced 536 m apart. A brick shot pattern was acquired to yield an average fold of 24 over 50 km^2. The entire survey was oriented N-S/E-W.

In this paper, three analysis techniques are presented which take advantage of the wide azimuth data to provide important attributes for characterizing fractures. Prior to analyzing PS-wave birefringence, azimuth-limited processing of the 3-D data was conducted. PS1 and PS2 directions were identified and used to optimally preserve the azimuthal effects of S-wave splitting (Van Dok and Gaiser, 2001). Also, 2Cx2C Alford (1986) rotation adapted for PS-waves (Gaiser, 1999) provided a means to combine the multi-azimuth data into a single 2Cx2C volume (the 4-components: PS11, PS12, PS21, and PS22).

Overburden Analysis

One of the most important steps in using PS-waves for fracture detection is to quantify the overburden azimuthal anisotropic properties and remove the detrimental effects S-waves suffer. These properties include the orientation of the principal S-wave directions, used to identify fast and slow waves for processing, and the differential velocity between the fast (PS1) and slow (PS2) waves. Using either azimuth supergatheres from preprocessing analyses or CDP-migrated data, these properties can be determined from 2Cx2C Alford rotation and Winterstein and Meadows (1991) layer-stripping methods.

Another important property of the overburden is the vertical extent. One approach to estimate the extent of S-wave azimuthal anisotropy in the overburden is to analyze PS1 and PS2 velocity ratios (Gaiser, 1996) as a function of two-way time. Figure 1 shows an analysis between the fast and slow data located at the well in the northern part of the survey. The vertical axis is PS2, two-way time and the horizontal axis is the ratio of Vps1/Vps2, average velocity. Variable density represents positive cross-correlation coefficients between the two waves. Depending on the velocity ratio, PS2 is stretched (< 1.0) or compressed (> 1.0), and then correlated with the PS1 at predefined window times. Contours superimposed on the plot indicate constant time delays of PS2 in milliseconds.

A maximum correlation trend can be clearly interpreted and is indicated by the dashed line. This corresponds to the time-variant velocity ratio of Vps1/Vps2. Above 1.0 s the trend is unknown. However, below 1.0 s the trend increases to a maximum at about 1.3 s and then roughly follows a 30 ms PS2 time delay. In the absence of the upper 1.0 s of data, the base of the overburden can be interpreted at about 1.5 s. It represents an interval of relatively homogeneous, azimuthally anisotropic material with constant orientation confirmed by azimuth-supergather analyses (Van Dok and Gaiser, 2001). Notice that the trend increases to the 40 ms PS2 time delay contour at about 2.5 s, indicating an increase in S-wave birefringence.

Further processing of the overburden involves layer stripping, or removing the azimuthal anisotropic effects imparted on the PS-wave data by this shallow interval. This can be accomplished over a time window from 0.0 to 1.6 s. The resulting fast S-wave direction and slow S-wave time delays of the overburden are smoothed spatially and then applied to the poststack data.
**Target Horizon Analyses**

After layer stripping the overburden, the data are in position for further analysis to determine principal S-wave directions and percent anisotropy for deeper intervals. Figure 2 shows the 2Cx2C-inline section that intersects the well at the vertical white line. $P_{S_{11}}$ and $P_{S_{22}}$ are the principal components and are aligned down to the base of overburden at about 1.6 s. Also, the off-diagonal components ($P_{S_{12}}$ and $P_{S_{21}}$) have been minimized down to this same event.

One approach to analyze target horizons below the overburden is to interpret residual amplitudes on the off-diagonal components spatially and temporally. These amplitudes result when there are changes in the S-wave birefringence properties, such as the increase at 2.5 s in Figure 1, or a change in the principal directions. Such changes may be too subtle to be quantified by traditional layer-stripping methods or the velocity ratios, but amplitudes are sensitive to these variations in S-wave properties and can give qualitative insights into regions where fracturing may be more intense or change orientation. Figure 3 shows example maps of residual amplitude at about 1.9 and 2.5 s (arrows in Fig. 2). The horizontal white line indicates the location of the inline data from Figure 2.

A more quantitative approach is to measure traveltimes between reflections bracketing targets for both the $P_{S_{11}}$ and $P_{S_{22}}$ waves in the volume in Figure 2. By comparing isochron differences between $P_{S_{11}}$ and $P_{S_{22}}$, a spatial representation of percent anisotropy can be interpreted for lateral variations in fracture intensity. The assumption here is that there is little or no change in the orientation of the principal axes, since rotations are not involved. Constant principal-axis directions are observed in azimuth-supergather analyses located at the two wells indicated in Figure 3.

The third approach, which is most quantitative, involves further layer stripping below the overburden. It is important to remember that the property we are analyzing for fracture detection is the transmission effect on S-waves: the birefringence orientation and the time separation. Off-diagonal components are minimized further by 2Cx2C Alford rotations to estimate any change in the direction of the principal axes. After minimization, the separated $P_{S_{11}}$ and $P_{S_{22}}$ waves are correlated and $P_{S_{22}}$ is aligned with $P_{S_{11}}$. These properties can then be interpreted as lateral variations in fracture orientation and intensity.

**Conclusions**

$V_{p_{11}}/V_{p_{22}}$ velocity ratio analysis is a valuable tool to quantify the vertical extent of S-wave birefringence as a function of time. As this ratio varies in time, it indicates different layers in the subsurface where birefringent properties may have changed. One of the most important of these layers is the overburden, which can be removed effectively by 2Cx2C Alford rotation and layer-stripping analyses, and leads to quantifying the fracture properties at target horizons. Three analysis techniques (residual off-diagonal amplitudes, $P_{S_{11}}$ and $P_{S_{22}}$ traveltime isochrons, and layer stripping) provide a broad range of interpretation tools and attributes that can help identify lateral variations in fracture properties.

**Acknowledgements**

We thank John Markert at WesternGeco for his help in processing the converted-wave data for this study. Thanks also to EOG Resources, Tom Brown Inc., and Basin Exploration for their participation and for providing valuable insights in the nature of the reservoir.

Figure 1. Average velocity ratio analysis between the PS$_{11}$ and PS$_{22}$ traces (left) located near the well in the northern part of the survey. The Vps$_{11}$/Vps$_{22}$ ratio ranges from 0.95 to 1.05, time is two-way PS$_{11}$, and variable density represents positive cross-correlation coefficients between PS$_{11}$ and PS$_{22}$. Contours indicate constant PS$_{22}$ time delays and the dashed line shows the interpreted relationship between the split S-waves. The base of the overburden is interpreted at the maximum traveltime difference just below the event at 1.3 s.
Figure 2. 2Cx2C inline section after Alford rotation and layer stripping the overburden. PS$_{11}$ and PS$_{22}$ are the principal components aligned through the overburden at about 1.6 s. These components are important for quantitative isochron analyses of percent azimuthal anisotropy. PS$_{12}$ and PS$_{21}$ are the off-diagonal components minimized through the overburden. Residual amplitudes below the overburden on PS$_{12}$ and PS$_{21}$ provide qualitative insights into changes in birefringence shown in Figure 3. The vertical white line indicates the location of the well and the V$_{ps_{11}}$/V$_{ps_{22}}$ average velocity analysis in Figure 1.

Figure 3. Attribute maps of residual amplitude from the off-diagonal components in Figure 2 at the two arrows. The horizontal white line shows the location of the 2Cx2C-inline section in Figure 2 intersecting the well at the center. High amplitude areas indicate qualitative changes in birefringence where S-wave splitting properties differ from that of the overburden properties. These areas could be related to either a change in the orientation of the principal axes or a change in the percent anisotropy.
